THE PROBLEM

1 in 160 chips fails.
Standard ML misses every single one.

What you see: Left bar chart: 49,686 pass samples vs 314 failures (1:158 ratio). Right pie chart: label noise breakdown with 42 Pass-as-Fail and 17 Fail-as-Pass noisy labels. Standard cross-entropy predicts "pass" for everything: 99.4% accuracy, 0% recall.

1:160	16M	$500K
Class imbalance	Training records	Cost per missed defect

Fix: **FocalLoss (α=0.75, γ=2.0)** — down-weights easy majority samples, forces learning on the hard minority. No SMOTE, no synthetic oversampling, no data leakage.

A100 GPU TRAINING

HybridTransformerCNN on NVIDIA A100-SXM4-40GB

What you see: Top left: loss convergence over 50 epochs with bfloat16. Top center: AUC-PR per epoch. Top right: precision-recall curves for val/test/unseen splits — near-identical, confirming no overfitting. Bottom: confusion matrices showing 3,374 true defects caught out of 15,595.

0.816	0.054	50
AUC-ROC	AUC-PR (key metric)	Epochs (best: 48)

CRITICAL ENGINEERING INSIGHT

The float16 Death Spiral that killed 4 training runs

✗ float16 + GradScaler

```
FocalLoss: (1-p)^γ
# 5-bit exp overflows
GradScaler ÷2 → ÷2 → ÷2
scale→0, loss collapses
```

✓ bfloat16 — No GradScaler

float16	5-bit exp = ±65,504
bfloat16	8-bit exp = $\pm 3.4 \times 10^{38}$

bfloat16 = float32 exponent range.
Focal gradients never overflow.

The fix: Changed from `torch.float16` to `torch.bfloat16` across 11 locations in 7 files. Removed GradScaler entirely. AUC-PR went from 0.001 (fully collapsed) to 0.054 — a 54x recovery. Hardware-aware numerical analysis applied to production training.

4	11	54×
Runs killed by float16	Locations changed	AUC-PR recovery

40-DAY PSI DRIFT HEATMAP

Drift escalated for 13 days.
Then the retrain gate opened.

What you see: PSI per feature per day. Green=stable, yellow=warning (PSI 0.1-0.2), red=critical (PSI >0.2). Cyan vertical at Day 30 marks the automated retrain. Orange vertical at Day 39 is the automatic rollback. Each row is one of 6 physical DRAM parameters.

D1-8 **Stable baseline.** All 6 features green. PSI < 0.05. Model v1 serving.

D9 **False alarm.** retention_time PSI=2.05 from transient batch. Auto-recovered Day 10.

D17-29 **Staleness block.** Real drift confirmed, PSI climbs to 4.9 but held by 30-day freshness guard.

D30 **RETRAIN TRIGGERED.** Max PSI 5.25. v2 trains on full 5M rows, canary passes, promoted.

D39 **ROLLBACK.** Bad checkpoint (AUC-PR 0.021 vs 0.054). Automatic revert same DAG cycle.

RETRAIN GATE — 3 CRITERIA

Drift alone caused 12 false triggers. All 3 gates prevented them.

What you see: Each bar chart is one retrain condition. Red=breached, green=not met. Retrain fires ONLY when all three are simultaneously red: >3 features with critical PSI, >5% AUC-PR drop vs baseline, AND >30 days since last retrain. Multi-gate logic prevented 12 spurious retrains.

Why 3 gates, not 1?

PSI alone fires on normal batch variance. Performance alone is noisy at 1:160 imbalance. Staleness alone wastes compute. Combined: precision retraining.

Engineering Decision ED-042

Low-data drift is **tagged but never triggers retraining.** When batch <10K rows, PSI is statistically unreliable. Tag in MLflow, wait for real data volume.

PRODUCTION INFRASTRUCTURE

6 services. One command. Fully orchestrated.

⚙ Apache Airflow

3 DAGs: daily_inference, retrain_trigger, simulation_master. True dependency graph with SLA monitoring and retry policies.

📨 Apache Kafka

Streaming DRAM test records. Consumer group routes records to FastAPI inference engine in real time.

⚡ Apache Spark

Batch ETL on 5M-row daily slices. 4.7× faster than pandas at this row count. Parquet output to S3.

📊 MLflow Registry

Tracks every run including the 4 failed float16 runs. Champion/challenger versioning with automatic rollback.

🔍 Prometheus + Grafana

Per-feature PSI dashboards. Inference latency p50/p95/p99. Real-time drift alerting.

🚀 FastAPI + K8s

120ms p99 latency under load. K8s HPA + canary deployment. Horizontal scaling for fab burst data.

To run locally: `cd deploy/docker && docker compose up -d` — all 6 services. Airflow at :8080, MLflow at :5001, Grafana at :3000, FastAPI at :8000/docs.

HARDWARE BENCHMARK

CPU training = 69 hours.
A100 = 1.6 hours. GPU is not optional.

What you see: Left: throughput — A100 delivers 88,128 samples/s, 49× faster than CPU (2,000/s). Right: time for 50 epochs — A100 completes in 1.6 hours, CPU would take 69.2 hours. For automated production retraining on Day 30, waiting 3 days for CPU is not an option.

88K/s	49×	219 min
A100 throughput (bfloat16)	A100 vs CPU speedup	40-day simulation total wall clock

Production path: **AWS g4dn.xlarge (T4, $0.526/hr)** for scheduled retrains. A100 Colab for initial training. Auto-stop script terminates EC2 after each run.

SIMULATION COMPLETE

200M rows. 40 days.
The pipeline held.

Final result: 200M rows processed, 8.5 GB Parquet on S3, 219 minutes wall clock on A100. 1 automated retrain (Day 30). 24 critical drift days. 1 canary failure + automatic rollback (Day 39). System self-healed with zero human interventions.

The model is rarely the bottleneck in production ML.

It is the drift strategy, the retrain gate,
and the rollback safety net that keep it reliable at day 40.
